Capstone Project

P6: Sberbank Russian Housing Market

Report

I. Definition

Project Overview

Regression analysis is a form of math predictive modeling which investigates the relationship between variables. It answers the questions: Which factors matter most? Which can we ignore? How do those factors interact with each other? And, perhaps most importantly, how certain are we about these factors and their predictions?

The main factor that we're trying to understand or predict is a target (a dependent variable). The features (independent variables) are the factors we suppose to have an impact on the dependent variable. Using this set of variables, we generate a function that maps inputs to outputs. The training process continues until the model achieves the desired level of accuracy.

The project investigates **supervised learning** as a part of regression analysis that uses a known (training) dataset to make predictions. This dataset includes input data and response values. The supervised learning algorithms seek to build models which make predictions of the response values for a new dataset. A test dataset is used to validate the model.

Housing costs are a sphere in the real economy for applying supervised learning. They demand a significant investment from both consumers and developers. And when it comes to planning a budget—whether personal or corporate—the last thing anyone needs is uncertainty about one of their budgets expenses. Sberbank, Russia's oldest and largest bank, helps their customers by making predictions about reality prices so renters, developers, and lenders are more confident when they sign a lease or purchase a building.

Although the housing market is relatively stable in Russia, the country's volatile economy makes forecasting prices as a function of apartment characteristics a unique challenge. Complex interactions between housing features such as a number of bedrooms and location are enough to make pricing predictions complicated. Adding an unstable economy to the mix means Sberbank and their customers need more than simple regression models in their arsenal.

The project was built on the basis of the competition offered on the site <https://www.kaggle.com>.

The most valuable side of this project is the investigation of real data and the attempt to approximate the predictions on them to the threshold of 0.7-0.8 for the coefficient of determination.

Problem Statement

Sberbank is challenging programmers to develop algorithms which use a broad spectrum of features to predict real prices. Algorithm applications rely on a rich dataset that includes housing data and macroeconomic patterns. An accurate forecasting model will allow Sberbank to provide more certainty to their customers in an uncertain economy.

My choice of the solution in this situation is to select the most correlated indicators with the target variable and apply ensemble algorithms that have repeatedly shown successful results in the study of price trends in real estate. Boosting and bagging methods combine several models at once in order to improve the prediction accuracy on learning problems with a numerical target variable.

Then I am going to explore the different types of neural networks in the sphere of regression predictions and try to achieve the same with ensemble methods level of model performance.

Metrics

The wide spectrum of popular metrics for regression was chosen and documented.

1. Explained variance regression score.

If \hat{y} is the estimated target output, y the corresponding (correct) target output, and Var is variance, the square of the standard deviation, then the explained variance is estimated as follow:

$$\text{explained_variance}(y, \hat{y}) = 1 - \frac{\text{Var}\{y - \hat{y}\}}{\text{Var}\{y\}}$$

2. Coefficient of determination.

If \hat{y}_i is the predicted value of the i -th sample and y_i is the corresponding true value, then the score R^2 estimated over n_{samples} is defined as

$$R^2(y, \hat{y}) = 1 - \frac{\sum_{i=0}^{n_{\text{samples}}-1} (y_i - \hat{y}_i)^2}{\sum_{i=0}^{n_{\text{samples}}-1} (y_i - \bar{y})^2} \quad \text{where} \quad \bar{y} = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} y_i$$

3. Mean squared error.

If \hat{y}_i is the predicted value of the i -th sample, and y_i is the corresponding true value, then the mean squared error (MSE) estimated over n_{samples} is defined as

$$\text{MSE}(y, \hat{y}) = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} (y_i - \hat{y}_i)^2$$

4. Mean absolute error.

If \hat{y}_i is the predicted value of the i -th sample, and y_i is the corresponding true value, then the mean absolute error (MAE) estimated over n_{samples} is defined as

$$\text{MAE}(y, \hat{y}) = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} |y_i - \hat{y}_i|$$

5. Median absolute error.

If \hat{y}_i is the predicted value of the i -th sample and y_i is the corresponding true value, then the median absolute error (MedAE) estimated over n_{samples} is defined as $\text{MedAE}(y, \hat{y}) = \text{median}(|y_1 - \hat{y}_1|, \dots, |y_n - \hat{y}_n|)$.

Evaluation metrics capture different properties of the prediction performance: how well the model explains the target variance and makes predictions, how far the predictions are from the real values. It allows us to choose the best algorithm by comparing many indicators.

II. Analysis

Data Exploration

The data for the investigation is a large number of economic indicators for pricing and prices themselves (train.csv and test.csv). Macroeconomic variables are collected in a separate file for transaction dates (macro.csv). In addition, the detailed description of variables is provided (data_dictionary.txt).

Sberbank Russian Housing, Dataset Descriptive Statistics:

```
Number of houses = 30471
Number of features = 44
Minimum house price = 100000
Maximum house price = 11111112
Mean house price = 7123035.28
Median house price = 6274411.00
Standard deviation of house prices = 4780032.89
```

For practical reasons, I have not analyzed all the data and have chosen the following independent variables:

1. the dollar rate, which traditionally affects the Russian real estate market;
2. the distance in km from the Kremlin (the closer to the center of the city, the more expensive);
3. indicators characterizing the availability of urban infrastructure nearby (schools, medical and sports centers, supermarkets, etc.) ;
4. indicators of a particular living space (number of rooms, floor, etc.);
5. proximity to transport nodes (for example, to the metro);
6. indicators of population density and employment in the region of housing accommodation.

All these economic indicators have a strong influence on price formation and can be used as a basic set for regression analysis. Examples of numerical variables: the distance to the metro, the distance to the school, the dollar rate at the transaction moment, the area of the living space. Examples of categorical variables: neighborhoods, the nearest metro station, the number of rooms.

Here data outliers are, in most cases, expensive price categories. They have a strong influence on the market prices in general, so I did not exclude them from the analysis but applied the necessary method of scaling the variables RobustScaler().

We should also note that the features are not normally distributed. But the log-normal distribution looks very similar to their properties.

The goal of the project is to predict the price of housing using the chosen set of numerical and categorical variables. The predicted target is not discrete, for the training set all the values of this dependent variable are given, and therefore it is necessary to apply the regression algorithms of supervised learning.

The data preprocessing confirmed the assumption: these variables are in a sufficiently strong relationship with the target variable. They are used as the basis for building different types of models in several forms: only numerical variables, numeric and categorical variables transformed into numeric or binary code.

Exploratory Visualization

To realize the project it was necessary to use a lot of visualization tools at all stages: data tables, distributions of quantities, correlation maps, the graphical comparison of predictions and real values, representation of the feature importance for specific algorithms, operation processes and architecture of neural networks, etc.

For example: the loss function (pic.1) displays the effectiveness of neural network training, the correlation matrix (pic.2) shows the strong relationship between many variables (positive and negative), feature importance (pic.3) explains the influence of each variable on the concrete regression model.

Algorithms and Techniques

To compare the prediction quality, I chose this set of tools.

1. ScikitLearn ensemble and neural network algorithms: Gradient Boosting Regressor, Bagging Regressor, MLP Regressor.
2. Keras: Dense, Flatten, Dropout, Convolutional, Max-Polling, LSTM layers and additional tools.
3. Numpy, Pandas, ScikitLearn: tools for data preprocessing.
4. Matplotlib, Seaborn: plots for data visualization.

In addition, I was wondering what the highest performance rate will be achieved by each of the presented algorithms and whether the predicted trends of price change for all used types of techniques will coincide.

The first group of algorithms was chosen from **ensemble methods**. It combines the predictions of several base estimators built with a given learning algorithm (Decision Tree) in order to improve generalizability and robustness over a single estimator. They work very well with financial data because of these characteristics.

The **Bagging Regressor** is an **averaging** ensemble method. It builds several estimators independently on random subsets of the original training set and then averages their predictions. As a result, the combined estimator is usually better than any single one because its variance is reduced.

The **Gradient Boosting Regressor** is a **boosting** ensemble method. It combines base estimators sequentially and one tries to reduce the bias of the final estimator (a powerful ensemble). The mechanism of the model consists of three important components: the loss function for checking how well our model predicts the outputs based on input values, the Decision Tree algorithms for making predictions, the additive mechanism for algorithms for minimizing the loss function. At each particular Gradient Boosting iteration, a new algorithm is trained with respect to the error that was learned so far. This procedure has the following steps: 1) add one algorithm that can reduce the loss function based on the current estimates (existing algorithms in the model are not changed); 2) use an effective procedure called gradient descent to minimize the loss; 3) repeat till the fixed number of algorithms are added or the loss reaches an acceptable level or the loss no longer improves on an external validation dataset. The result of the model training should be that predictions slowly converge toward observed values.

Neural networks such as multi-layer perceptrons (**MLP**), convolutional neural networks (**CNN**), recurrent neural networks (**RNN**) were built from layers:

- **Dense** (fully connected) layers compute the output scores, resulting in volume of size. Each neuron in these layers are connected to all the numbers in the previous volume.
- **Activation** applies the certain activation function to an output.
- **Dropout** layers consist in randomly setting a fraction rate of input units to 0 at each update during training time, which helps prevent overfitting.
- **Flatten** layers flatten the input and collapses it into the one-dimensional feature vector.
- **Convolutional** layers Conv1D (temporal convolution) convolve the filter with the signal, i.e. "is sliding over the signal vector, computing dot products". Here the filter is an integer, the dimensionality of the output space (i.e. the number output of filters in the convolution) and the kernel size is an integer, specifying the length of the 1D convolution window.
- **Max-Polling** layers MaxPolling1D layers perform a downsampling operation along the temporal data. Max-pooling partitions the input signal into a set of non-overlapping samples and, for each such subsample, outputs the maximum value.
- **Recurrent** Layers LSTM (Long-Short Term Memory) are a type of artificial neural network designed to recognize patterns in sequences of data, such as numerical times series. Recurrent Layers possess a certain type of memory. For example, LSTMs contain information outside the normal flow of the recurrent network in a gated cell. Information can be stored in, written to, or read from a cell, much like data in a computer's memory. The cell makes decisions about what to store, and when to allow reads, writes and erasures, via gates that open and close. Unlike the digital storage on computers, however, these gates are analog, implemented

with element-wise multiplication by sigmoids, which are all in the range of 0-1. Analog has the advantage over digital of being differentiable, and therefore suitable for backpropagation.

Benchmark

The benchmark regressor among investigated models is the Gradient Boosting algorithm. It has the best level of all the evaluation metrics. We should notice that the Bagging algorithm results are really close to Gradient Boosting.

The Convolutional Neural Networks (CNN model) for 36 numeric and encoded categorical features demonstrates the best predictions among neural networks.

```
def cnn_model():
    model = Sequential()

    model.add(Conv1D(36, 3, padding='valid', activation='relu', input_shape=(36, 1)))
    model.add(MaxPooling1D(pool_size=2))

    model.add(Flatten())

    model.add(Dense(512, activation='relu', kernel_initializer='normal',))
    model.add(Dropout(0.5))

    model.add(Dense(1, kernel_initializer='normal'))

    model.compile(loss='mse', optimizer='rmsprop', metrics=['mae'])
    return model
```

Layer (type)	Output Shape	Param #
conv1d_7 (Conv1D)	(None, 34, 36)	144
max_pooling1d_7 (MaxPooling1D)	(None, 17, 36)	0
flatten_7 (Flatten)	(None, 612)	0
dense_162 (Dense)	(None, 512)	313856
dropout_20 (Dropout)	(None, 512)	0
dense_163 (Dense)	(None, 1)	513

Total params: 314,513
Trainable params: 314,513
Non-trainable params: 0

III. Methodology

Data Preprocessing

Data processing consisted of the following important steps:

1. deleting rows with a lot of missing data;
2. filling a small amount of missing data by linear interpolation;
3. the addition of a macroeconomic indicator;
4. transforming categorical variables into discrete numerical and binary encoded features;
5. checking the coding and eliminating the differences between the category variables in the training and test sets.

Implementation

In this project, I have used the following versions of software libraries: Scikit-Learn - 0.19.0, Keras - 2.0.4, Numpy - 1.13.1, Pandas - 0.20.2, Matplotlib - 2.0.2, Seaborn - 0.7.1.

The architecture of each network is implemented as a function consisting of a sequence of layers. For example:

Such a wide range of algorithms allowed to determine the approximate level of the achievable coefficient of determination of test predictions for this data set: 70-72%. Identifying the most effective algorithms in the sphere of real financial indicators is also an important task for machine learning in general.

Refinement

Algorithms	Initial Parameters	Final Parameters	R2		MSE

CNN	Dense(128)	Dense(512)=>Dropout(0.5)	0.6894	0.7033	0.6212	0.5935
RNN	LSTM(636)	LSTM(159), LSTM(636)	0.6529	0.7093	0.6943	0.5816

As a final visualization, I chose the image of the predictions of all models on a single graph. As it can be seen from the illustrations, the predictions are very close to each other and determine the overall price dynamics quite clearly. This is an additional confirmation of the reliability of predictions: in case of erroneous conclusions, all models would hardly have demonstrated the same trend.

Pic. 4. Display all predictions

Reflection

The prediction of financial values is quite complex due to the strong dependence of the indicators on each other, the influence of the time factor and uncertainty. To achieve a greater approximation to real data is one of the closest and achievable tasks of machine learning.

The project database is similar to the well-known and well-studied the Boston Housing Dataset. Therefore, it was easy to start implementing the project by applying similar methods. In the course of working on the project, I experienced much more regression algorithms and neural networks than presented in the program part, then just shortened the list, leaving the most effective. Working on the data also did not present any particular difficulties: firstly I cleaned and reduced the base, then tried to use only the numerical variables, and finally added categorical ones and compared the results.

The most interesting aspect for me was to work with the project precisely because of the large range of variables in real data and the possibility to advance the understanding this field of activity.

Improvement

There are many possible ways to improve the modeling: studying of other sets of variables (maybe some variables with important information were lost), combining of existing algorithms in ensembles (to catch the trend more effective), developing the architecture of built neural networks in the project (improving structures allow to analyze more deeply), applying the existing neural networks with a complex structure from the external sources (for the same reason), etc.
